Pricing American Options

M. Haugh G. Iyengar

Department of Industrial Engineering and Operations Research
Columbia University

Pricing American Options

- Can also price American options in same way as European options
 - but now must also check if it's optimal to **early exercise** at each node.
- But recall never optimal to early exercise an American call option on non-dividend paying stock.

e.g. Price American put option: expiration at $t = 3$, $K = \$100$ and $R = 1.01$.

Pricing American Options

- Price option by working backwards in binomial the lattice.

$$\text{e.g. } 12.66 = \max \left[12.66, \frac{1}{R} (q \times 6.54 + (1 - q) \times 18.37) \right]$$

A Simple Die-Throwing Game

Consider the following game:

1. You can throw a fair 6-sided die up to a maximum of three times.
2. After any throw, you can choose to 'stop' and obtain an amount of money equal to the value you threw.

e.g. if 4 thrown on second throw and choose to 'stop', then obtain \$4.

Question: If you are risk-neutral, how much would you pay to play this game?

Solution: Work backwards, starting with last possible throw:

1. You have just 1 throw left so fair value is 3.5.
2. You have 2 throws left so must figure out a **strategy** determining what to do after 1st throw. We find

$$\text{fair value} = \frac{1}{6} \times (4 + 5 + 6) + \frac{1}{2} \times 3.5 = 4.25.$$

3. Suppose you are allowed 3 throws. Then ...

Question: What if you could throw the die 1000 times?

Replicating Strategies in the Binomial Model

M. Haugh G. Iyengar

Trading Strategies in the Binomial Model

- Let S_t denote the stock price at time t .
- Let B_t denote the value of the cash-account at time t
 - assume without any loss of generality that $B_0 = 1$ so that $B_t = R^t$
 - so now explicitly viewing the cash account as a security.
- Let x_t denote # of shares held between times $t - 1$ and t for $t = 1, \dots, n$.
- Let y_t denote # of units of cash account held between times $t - 1$ and t for $t = 1, \dots, n$.
- Then $\theta_t := (x_t, y_t)$ is the portfolio held:
 - (i) immediately **after** trading at time $t - 1$ so it is known at time $t - 1$
 - (ii) and immediately **before** trading at time t .
- θ_t is also a **random process** and in particular, a **trading strategy**.

Trading Strategies in the Binomial Model

Self-Financing Trading Strategies

Definition. The **value process**, $V_t(\boldsymbol{\theta})$, associated with a trading strategy, $\boldsymbol{\theta}_t = (x_t, y_t)$, is defined by

$$V_t = \begin{cases} x_1 S_0 + y_1 B_0 & \text{for } t = 0 \\ x_t S_t + y_t B_t & \text{for } t \geq 1. \end{cases} \quad (3)$$

Definition. A **self-financing** trading strategy is a trading strategy, $\boldsymbol{\theta}_t = (x_t, y_t)$, where changes in V_t are due entirely to trading gains or losses, rather than the addition or withdrawal of cash funds. In particular, a self-financing strategy satisfies

$$V_t = x_{t+1} S_t + y_{t+1} B_t, \quad t = 1, \dots, n-1. \quad (4)$$

The definition states that the value of a self-financing portfolio **just before** trading is equal to the value of the portfolio **just after** trading

– so no funds have been deposited or withdrawn.

Self-Financing Trading Strategies

Proposition. If a trading strategy, θ_t , is self-financing then the corresponding value process, V_t , satisfies

$$V_{t+1} - V_t = x_{t+1}(S_{t+1} - S_t) + y_{t+1}(B_{t+1} - B_t)$$

so that changes in portfolio value can only be due to capital gains or losses and not the injection or withdrawal of funds.

Proof. For $t \geq 1$ we have

$$\begin{aligned} V_{t+1} - V_t &= (x_{t+1}S_{t+1} + y_{t+1}B_{t+1}) - (x_{t+1}S_t + y_{t+1}B_t) \\ &= x_{t+1}(S_{t+1} - S_t) + y_{t+1}(B_{t+1} - B_t) \end{aligned}$$

and for $t = 0$ we have

$$\begin{aligned} V_1 - V_0 &= (x_1S_1 + y_1B_1) - (x_1S_0 + y_1B_0) \\ &= x_1(S_1 - S_0) + y_1(B_1 - B_0). \end{aligned}$$

□

Risk-Neutral Price \equiv Price of Replicating Strategy

- We have seen how to price derivative securities in the binomial model.
- The key to this was the use of the 1-period risk neutral probabilities.
- But we first priced options in 1-period models using a replicating portfolio
 - and we did this without needing to define risk-neutral probabilities.
- In the multi-period model we can do the same, i.e., can construct a self-financing trading strategy that replicates the payoff of the option
 - this is called **dynamic replication**.
- The initial cost of this replicating strategy must equal the value of the option
 - otherwise there's an arbitrage opportunity.
- The dynamic replication price is of course equal to the price obtained from using the risk-neutral probabilities and working backwards in the lattice.
- And at any node, the value of the option is equal to the value of the replicating portfolio at that node.

The Replicating Strategy For Our European Option

Key: Replicating strategy $\equiv [x_t, y_t]$
 Option price $\equiv C_t$
 Stock price $\equiv S_t$

The Replicating Strategy For Our European Option

Key: Replicating strategy $\equiv [x_t, y_t]$

Option price $\equiv C_t$

Stock price $\equiv S_t$

e.g. $\cdot 802 \times 107 + (-74.84) \times 1.01 = 10.23$ at upper node at time $t = 1$
